The following three descriptors are used to characterize flaming combustion (Figure 1):

1) **Flame height** is the vertical distance from the base to the tip of the flames.
2) **Flame length** is the actual length of the flames from the tip to the midpoint of the flame footprint. Under no-wind conditions on flat ground, flame length equals flame height. Otherwise flame length will exceed flame height regardless of whether a fire is backing or heading.
3) **Flame zone depth** is the distance from the leading edge to the trailing edge of the flaming front measured at the base of the flames.

Byram (1959) established the mathematical relationship between flame height (wind speed = 0) and the depth of the flame-zone showing the dimensionless ratio was a straight line function of the weight of fuel burning per unit area. That means the more fuel burning in a square foot, the higher the flames will be and the deeper the flame zone.

From a physics standpoint, increasing wind speed will decrease flame height because the wind will bend the flames over. But in the real world, as wind speed increases so does rate of spread, which in turn increases fireline intensity. As more understory fuels are involved, flame height will increase accordingly (although it will be less than flame length). Wind pushing a headfire tilts the flames ahead toward unburned fuel, subjecting the fuel to increased radiant heat, thereby preheating it and raising it to ignition temperature (~500°F) more quickly than with no-wind conditions. This results in more rapid fire spread and as rate of spread increases, so does flame length and fireline intensity. In topography, the steeper the slope, the closer the flames are to the upslope fuel (Figure 2).

---

**Figure 1.** Idealized cross-sections of a surface head fire in grass fuels on level terrain. Figure modified from Alexander et al. (2009); originally in Cheney & Sullivan (2008).
Upslope wind bends the flames even closer to the slope surface resulting in even faster uphill spread. Wind speed has little effect on backfire rate of spread; even though flame length will increase, the flames lean back into the burned area.

Visually estimating flame length is usually as much a “guesstimate” as an estimate because flame length continuously changes in response to wind speed and the amount, size, continuity, and arrangement of fuel. When making notes to be included in the written evaluation of a burn, an approximation to the nearest ½ foot for flames less than 2 feet high, 1 foot for flames 2 to 10 feet high, and 2 feet for flames 10 to 15 feet high will suffice. Some burners also include the maximum length and height observed in parentheses directly following the average length and height with the notations “BF” for backfire and “HF” for headfire.

ACKNOWLEDGMENTS
Over a decade ago, Paula Seamon encouraged me to write a series of short summaries of prescribed fire topics. I finally ran out of excuses Paula. The author thanks Marty Alexander, Ralph Nelson, and Alan Long for their careful review of this factsheet and Annie Oxarart for her editing, design, and layout skills and especially her patience in dealing with my continual suggestions.
